## BACKGROUND

- Geriatric depression affects approximately 5% of older adults (age ≥65 years) in the United States and is associated with longer length of illness, increased number of depressive episodes, a greater risk of comorbidities, and age-related changes in pharmacokinetics (i.e. reduced renal excretion).
- Challenges in medication prescribing include increased polypharmacy/drug-drug interactions, lower adherence, and higher adverse event rates.
- Combinatorial pharmacogenomic (PGx) testing may inform more precise prescribing by identifying adverse gene-drug interactions (GDI).

## OBJECTIVES

• We evaluated the utility of a combinatorial PGx test in patients from the **G**enomics **U**sed to **I**mprove **DE**pression **D**ecisions (GUIDED) trial who were ≥65 years of age.

# METHODS

### COHORT

- The GUIDED trial was a 24-week randomized controlled trial including patients who were diagnosed with major depressive disorder (MDD). Patients were required to have a minimum of 1 prior medication failure, with an average of 3.5 failed medication trials in the cohort.
- All patients received combinatorial PGx testing and were randomized 1:1 to guided-care (test results available to inform medication selection) or treatment as usual (TAU).
- Only guided-care physicians had access to the test report before week 12.
- Patients and outcome assessment scale raters were blinded to study arm through week 8.
- Patients ≥65 years at the screening visit were included for analysis (n=206; 98 for guided-care, 108 for TAU) (Table 1).

#### COMBINATORIAL PGx TESTING

Significant GDI	Use with increased caution and with more frequent monitoring
Moderate GDI	Use with caution
No GDI	Use as directed

- Combinatorial PGx testing included evaluation of 8 pharmacokinetic and pharmacodynamic genes (CYP1A2, CYP2C9, CYP2C19, CYP3A4, CYP2B6, CYP2D6, HTR2A, SLC6A4).
- GDI for each medication were determined based on an algorithmic assessment of individual genotypes.
- Medications were categorized according to the level of predicted GDI.

#### ANALYSIS

- Patient outcomes were assessed using the 17-item Hamilton Depression Rating Scale (HAM-D17):
- Symptom Improvement: Percent decrease in HAM-D17 score from baseline
- Response: ≥50% decrease in HAM-D17 score from baseline
- Remission: HAM-D17 score ≤7

# RESULTS

- At week 8, there was an improvement in patient outcomes in the guided-care arm compared to TAU (Figure 1).
  - This was significant for response and remission.
- Outcomes in the guided-care arm showed continued improvement through week 24, indicating durability of the effect (Figure 2).
- By week 8, more than twice as many patients in the guided-care arm had switched to medications predicted by the test to have no genedrug interactions than in TAU (p < 0.001), indicating that clinicians followed the test report recommendation (Figure 3).
  - Combinatorial PGx-guided medication selection likely drove the significant increases in response and remission rate versus TAU.

# CONCLUSIONS

- Combinatorial PGx testing to inform medication selection improved outcomes among older adults with MDD in GUIDED.
- The marked improvements in response and remission rates in the guided-care arm support the clinical utility of the combinatorial PGx test in a population of patients who can be challenging to treat.

Currently under review for publication.
